Introduction

Among residential properties sold in Ames, Iowa, during 2006-2010, does the association between above-ground living area and sale price differ by dwelling type, after adjustment for lot area, construction quality, age, basement area, garage capacity, neighborhood, and sale year? Sale price is the recorded transaction amount in nominal US dollars. Rather than assuming a universal price-per-square-foot relationship, we estimate the adjusted sale-price difference associated with 100 additional square feet within each dwelling type. These estimates describe associations, not the causal return from enlarging a home.

Housing attributes need to be considered jointly, and past research highlights several key variables. Mathur (2019), studying King County, Washington, found that construction quality and maintenance were associated with higher prices. A medium-quality home sold for approximately 25% more than a low-quality home. This supports adjustment for quality, while the maintenance findings motivate considering condition in subsequent models. Goodman and Thibodeau (1995) analyzed nearly 8,500 Dallas single-family transactions. They found nonlinear depreciation and age-related heteroskedasticity. These findings motivate including age and checking both functional form and residual variance. Fik et al. (2003), studying the Tucson housing market, found that location and housing attributes jointly influenced prices in ways that simple location indicators did not fully capture. This motivates neighborhood adjustment, while recognizing that spatial dependence may remain.

Together, these studies support an adjusted analysis while warning against a universal price-per-square-foot rule. Our extension asks whether the living-area slope varies across five recorded dwelling types in Ames. We hypothesize that differences in layout and shared structures make a common slope too restrictive. We build on those studies by comparing what an extra 100 square feet means for the sale price of a detached home, a duplex, or a townhouse in Ames.

Multiple linear regression estimates conditional mean-price differences while adjusting for several characteristics simultaneously. A correlation or comparison of group means cannot isolate the adjusted area association or test whether slopes differ. Type-specific slopes, confidence intervals, and a joint partial F-test of the four interaction coefficients answer the question. The outcome is sufficiently continuous for this approach, subject to diagnostic assessment. An appraiser comparing historical Ames sales could use these estimates to judge whether 100 additional square feet carried the same price difference for a duplex as for a detached home. Our estimates reflect sales in Ames from 2006 to 2010. The same amount of space may be priced differently today or in another city.

Data description

We downloaded the original tab-delimited data and codebook from the Journal of Statistics Education archive (De Cock, 2011a, 2011b). The Ames City Assessor's Office originally recorded property characteristics and sales for valuation and assessment. De Cock obtained a records-system extract, removed specialized assessment variables and nonresidential records, and retained the latest transaction for repeatedly sold properties. His public release contains 2,930 properties and 82 fields and was curated for regression teaching.

The analysis uses 2,928 complete records, excluding one missing basement area and one missing garage capacity. Sale price has mean $180,841, median $160,000, standard deviation $79,890, and range $12,789-$755,000. Its many possible values support a continuous response; right skew does not itself invalidate regression, whose assumptions concern conditional errors. Unique parcel identifiers reduce repeated-property dependence, but neighboring homes and common market conditions can still produce dependent errors.

Nine predictors enter the model: living area, dwelling type, lot area, overall quality, age at sale, basement area, garage capacity, neighborhood, and sale year. Dwelling type and neighborhood are nominal; sale year is a factor. Quality is provisionally treated as a numerical 1-10 score, imposing equal increments. Living area is measured per 100 square feet and centered at 1,500 square feet; lot area is per 1,000 square feet and basement area per 100 square feet. These unit changes do not repair model assumptions.

The living-area-by-dwelling-type interaction allows different slopes for detached homes, converted two-family homes, duplexes, and interior/end-unit townhouses. These are existing categories, so no arbitrary numerical cutoffs are needed. Figure 2 displays the adjusted slopes; differing layouts provide the substantive motivation.

Table 1. Complete-case summaries. Prices and areas have long upper tails. Original missing counts: basement area 1, garage capacity 1; all other selected variables 0. One age equals -1; retain for investigation. Dwelling types are imbalanced; Landmrk has one observation.

Ethics discussion

The Ames City Assessor's Office recorded actual property sales. De Cock (2011b) documented their origin and published a codebook that distinguishes partial sales from other transactions. We consider the records trustworthy for studying associations among Ames sales in 2006–2010. The three unusually low prices for large homes illustrate why even a correctly recorded sale may be a poor measure of market value.

The assessor collected records for administrative purposes, and De Cock curated them for teaching. That documented purpose supports our classroom use, but the documentation does not establish what owners were told or whether they consented to secondary use. We therefore cannot verify every aspect of the original collection. Parcel identifiers can connect a sale to a household. We will credit the assessor and curator, avoid linking parcels to owners, and report group estimates. A neighborhood represented by one sale warrants particular care: we will avoid publishing its parcel details or interpreting its coefficient as a community characteristic.

Preliminary results

The preliminary model (Table 2) regresses sale price on nine predictors plus a living area × dwelling type interaction (adjusted $R^2 = 0.839$; residual SE = \$32,073).

For detached homes, 100 additional square feet is associated with a \$4,860 higher mean price (95% CI \$4,507–\$5,212), holding other predictors fixed. The corresponding slopes are \$2,419 for two-family conversions, \$1,900 for duplexes, \$1,832 for interior townhouses and \$6,042 for end-unit townhouses (Figure 2). The preliminary F-test suggests that the area slopes differ across dwelling types ($F(4, 2882) = 9.20$, $p < 0.001$). The widening residual spread in Figure 1b makes the p-value and confidence intervals provisional.

Figure 3 summarizes pairwise associations among the numeric predictors. At high fitted prices, observed prices bend above the identity line (Figure 1a). Residuals curve against fitted price (Figure 1b), living area (1c), and basement area (1g), suggesting that the model misses some nonlinear structure. Constant variance is violated: residual spread increases with fitted price (Figure 1b). Uncorrelated errors appear reasonable: residuals show no trend over sale time (Figure 1l), though nearby homes may share unmeasured influences. Normality is violated: the Q-Q plot (Figure

1m) shows heavy tails. The three largest negative residuals (rows 1499, 2181 and 2182) are partial sales above 4,000 square feet, which De Cock (2011b) flags as unlikely to reflect market value; Landmrk has a single sale (leverage one, Figure 1n). No corrections are applied at this stage.

The quality coefficient ($15,672 per point) agrees in direction with Mathur (2019), the negative age coefficient (−$404 per year) is consistent with depreciation reported by Goodman and Thibodeau (1995), though our residual spread is largest for newer homes, and large neighborhood effects echo Fik et al. (2003). Unexpectedly, end-unit townhouses have a larger estimated slope than detached homes, but the difference is not significant (95% CI −$326 to $2,690). GrnHill (2 sales) and Landmrk (1) give unstable estimates.

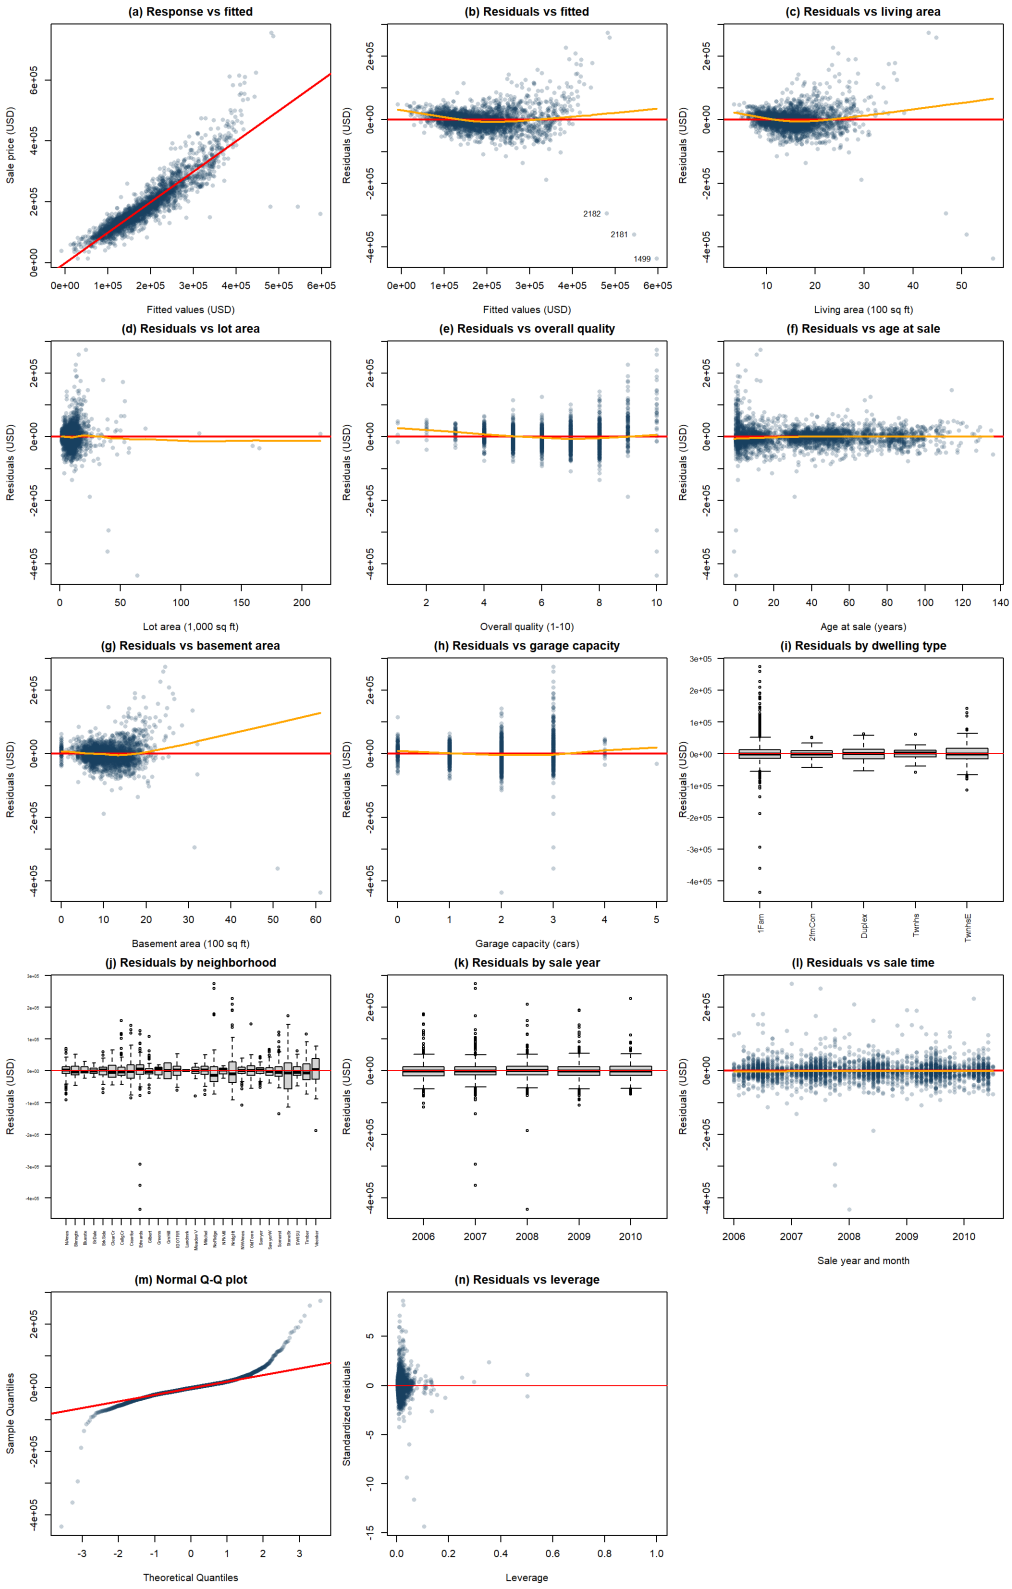

Figure 1: Residual diagnostics for the preliminary sale-price model. Residuals curve and spread out at higher fitted prices (b), and the normal Q-Q plot shows heavy tails (m). Orange curves show local trends. Labels in (b) identify the three most negative residuals by original data row.

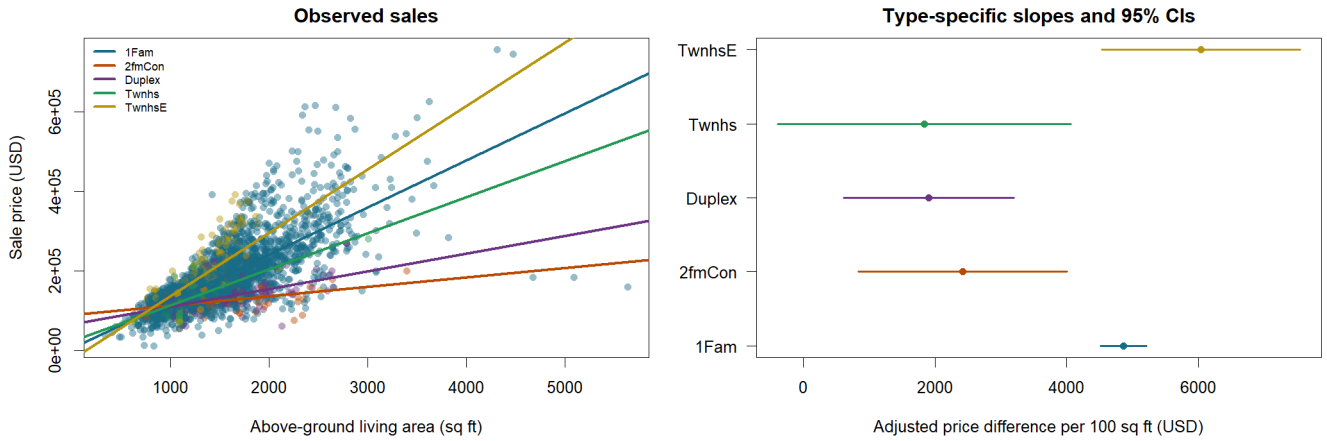

Figure 2: Observed sales with a least-squares line for each dwelling type (left) and adjusted living-area slopes with 95% CIs (right).

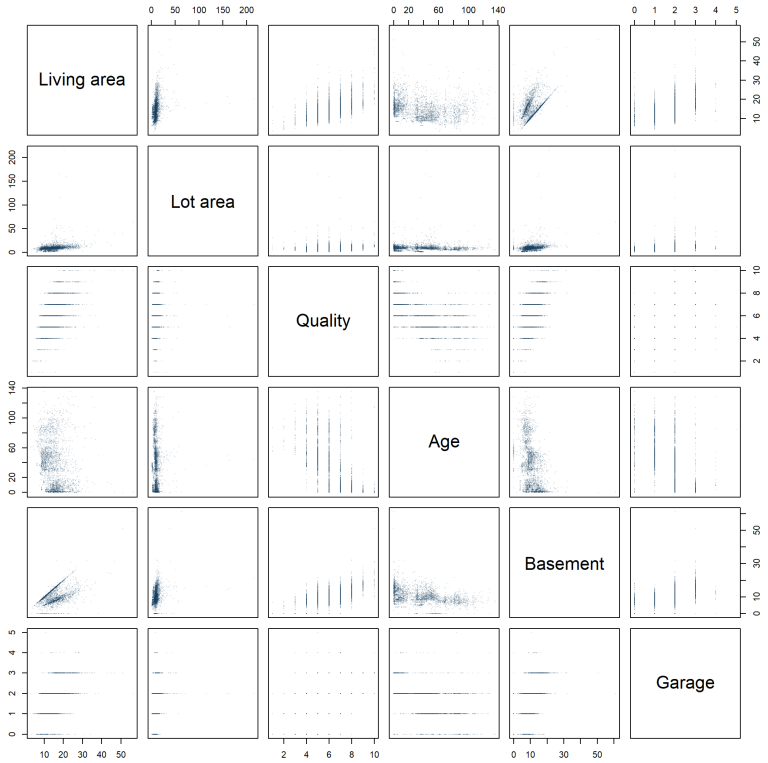

Figure 3: Pairwise scatterplots of the numerical predictors.

Table 2. Preliminary model, USD. References: detached home, North Ames, 2006. Dwelling-type contrasts are at 1,500 sq ft; interactions are slope differences per 100 sq ft. Neighborhood and sale-year effects are included but not shown.

Term	Estimate	SE	95% CI
Intercept	49,004	5,801	[37,630, 60,378]
Living area (per 100 sq ft, centred at 1,500)	4,860	180	[4,507, 5,212]
Type: two-family conversion	-9,749	4,279	[-18,139, -1,360]
Type: duplex	-21,566	3,426	[-28,285, -14,848]

Term	Estimate	SE	95% CI
Type: townhouse (interior)	-46,392	4,828	[-55,860, -36,924]
Type: townhouse (end unit)	-24,725	3,104	[-30,811, -18,639]
Lot area (per 1,000 sq ft)	529	88	[356, 702]
Overall quality (per point)	15,672	765	[14,172, 17,172]
Age at sale (per year)	-404	46	[-493, -314]
Basement area (per 100 sq ft)	2,260	182	[1,903, 2,617]
Garage capacity (per car)	10,229	1,110	[8,052, 12,406]
Living area x two-family conversion	-2,441	820	[-4,050, -833]
Living area x duplex	-2,959	674	[-4,280, -1,638]
Living area x townhouse (interior)	-3,028	1,147	[-5,277, -778]
Living area x townhouse (end unit)	1,182	769	[-326, 2,690]

Plan

We will retain living area, dwelling type, and their interaction because our question compares area slopes across types. Neighborhood and sale year will remain controls for location and market timing. Mathur (2019) motivates testing whether overall condition adds information beyond quality. Once diagnostics support inference, we will use partial F-tests to compare nested models fitted to the same sales on the same response scale. We will compare the model with and without condition. To assess simplification, we will test removing basement area and garage capacity jointly and check how much the estimated dwelling-type slopes change before dropping either control.

Figure 1b shows residual spread increasing with fitted price. We will try log price and use a Box–Cox profile to assess whether a log transformation is plausible. If curvature against living area persists (Figure 1c), we will try a squared centered-area term while retaining its linear term. After each refit, we will inspect residuals against fitted values and predictors for curvature and changing spread, the normal Q–Q plot for heavy tails, and residuals in sale order for dependence. We will compare slopes with and without the three flagged partial sales to see how sensitive our answer is to their inclusion. If we select log price, we will express area contrasts as percentage differences.

By November 15, [Members A/C] will complete diagnostics and model comparisons. By November 20, [Members B/D] will check interpretations and finish the poster. All members will rehearse and record by November 25, then verify the files by November 28.
